Abstract

A Hodgson's hawk-eagle (Spizaetus nipalensis) reared by a falconer showed severe weakne l-meat diet. Serologi hypopho nonstrated severe o steoclastic bone res one contai rophy and hype econdary hyperpa

Nutritional secondary hyperparathyroidism caused by long term deficiency of vitamin D_3, calcium or phosphorus, or by imbalances in the last two nutrients causes excessive production of parathyroid hormone (PTH), resulting in osteoclastic bone absorption (Woodard, 1997). Rickets, which has the same pathogenesis, occurs in various kinds of young birds and mammals and is well described (Whitehead & Wilson, 1992; Thorp, 1994). However, description of osteodystrophia fibrosa (fibrous osteodystrophy) in avian species is limited (Long et al., 1983). Here, we describe the disease secondary to nutritional hyperparathyroidism in a Hodgson's hawk-eagle (Spizaetus nipalensis) bred for falconry.

2 Materials and Methods

Necropsy was performed and the liver, kidneys, heart, lungs, intestine, pancreas, adrenal glands, thyroid glands, parathyroid glands, sternum, femur, tibiotarsus and skeletal muscles were routinely fixed in 10% neutral buffered formalin, embedded in paraffin wax and stained with haematoxylin and eosin. Selected samples of the sternum, femur and tibiotarsus were decalcified by formic acid before embedding.

and calcium compound by oral administration. Biochemical examination eight days later revealed lower serum calcium (72.0 µg/ml) and phosphorus (29.0 µg/ml) and higher alkaline phosphatase (ALP) (3100 IU/l) than normal. Normal ranges of these inorganic substances or enzyme in raptors are 89.3–101.9 µg/ml (calcium), 30.3–43.4 µg/ml (phosphorus) and 31–257 IU/l (ALP), respectively (Samour, 2000). The bird died ten days after the initial examination.

Gross examination confirmed that bone was very fragile with multiple complete and/or incomplete fractures. The parathyroid glands were bilaterally enlarged, up to 6 mm in diameter, and they were even larger than thyroid glands.

Histological changes of the affected bone mainly consisted of osteomalacic lesions and fractures. The former was characterized by a significant decrease in the amounts of mineralized trabecular bone associated with an increase in the width of unmineralized osteoid (Fig. 1). The osteoid borders were occasionally lined by osteoblasts and distinct osteoid seams were recognized. These changes occurred in the cortical and cancellous bone of the sternum, femur and tibiotarsus. The cortical bones of the diaphyses were also markedly thinned with dilation of the Haversian canals. The femur and tibiotarsus partly showed subperiosteal proliferation of trabeculae and loose fibrous tissue (Fig. 2). In addition, numerous osteoclasts were frequently observed on the surface of the trabeculae, Haversian canals and endosteum and fibrous tissue proliferated between these trabeculae (Fig. 3), suggesting a progression to osteodystrophia fibrosa. Although there were endochondral and membranous ossifications in and around the necrotic bone of each fracture, mineralization was incomplete in these foci. Enlarged parathyr ch had lightly e ands were atrophic

Osteodystrophia fibrosa is the result of continuous and excessive secretion of PTH and is characterized by marked osteoclastic resorption and fibrous replacement (Palmer, 1991). Locomotory disorders with fractures in birds of prey including those for falconry, have been reported as "cramps" or "fits"; protracted dietary deficiency of calcium or imbalance of calcium/phosphorus ratio has been considered important causative factors (Wallach & Flieg, 1970; Cooper, 1975). However, pathological descriptions of osteodystrophia fibrosa due to nutritional secondary hyperparathyroidism have rarely been reported in avian species (Long et al., 1983).

The present case was considered nutritional secondary hyperparathyroidism that resulted in severe osteodystrophia fibrosa. The active osteoclastic bone resorption and fibrous tissue proliferation between trabeculae in the examined bones are characteristic findings of osteodystrophia fibrosa. On the other hand, accumulation of osteoid and formation of osteoid seams in the medullary cavity are specific features of osteomalacia, which frequently progresses to osteodystrophia fibrosa when severe hyperparathyroidism develops in the course of the disease (Woodard, 1997). Compensating subperiosteal bone proliferation occurs in some cases of osteopoenia (Riddell, 1996). However, subperiosteal proliferation of osteoid and fibrous tissues in the present case was considered as unmineralized reactive callus resulting from microscopic fractures, because it was observed only in part of the femur and tibiotarsus.

The calcium: phosphorus ratio (Ca: P) of meat and fish commonly fed to birds of prey range from 1: 17 to 1: 44 whereas the correct Ca: P ratio for avian diets is listed as 1.5: 1 (Walla s in these diets ma in addition to an ab of the parathyr

For a long time, falconry has been maintained throughout the world as a traditional form of hunting and the avian species used include hawks, eagles, buzzards and peregrines. Dietary requirements of raptors have not been sufficiently studied, but artificial diets such as muscle meat and eviscerated prey are known to lack vitamins, calcium and phosphorus and may cause various metabolic bone diseases in raptors (Keymer, 1972; De Water, 1996). Investigation of the dietary requirements of raptors is essential to preserve these rare birds.
